Why Is It Important to Monitor the Levels of Toxic Chemicals in Blue Mussels in Casco Bay?

The common blue mussel, *Mytilus edulis*, is long lived and sedentary as an adult, accumulating local contaminants through feeding and surface contact. It is common throughout Gulf of Maine coastal areas where it is found in densely populated beds in the intertidal zone—the area between low and high tides. Casco Bay is one of the most productive areas in Maine for wild mussels. The blue mussel is thus a useful “sentinel” species for the Bay. Because many toxic compounds biomagnify (become more concentrated in organisms higher up the food chain), elevated levels of contaminants in the tissues of blue mussels—which are near the base of the food chain—suggest that top-level consumers, including fish and humans, may be at risk from contaminants in the ecosystem.

Data on toxic compounds in mussels from Casco Bay come primarily from statewide and regional monitoring programs. Maine DEP began using *Mytilus edulis* as an indicator species of toxic exposure in 1987, and has analyzed their soft tissues from approximately 65 sites along the Maine coast over the past 23 years. CBEP has periodically provided funding to add additional sites in Casco Bay to the program. Gulfwatch, a joint US/Canada blue mussel monitoring program, began sampling US and Canadian waters in 1991.

Status of Casco Bay Mussels

**DEP SWAT Program 2007–2009 Sample Collection**

Samples were collected by DEP from sites in Casco Bay in 2007, 2008 and 2009 (see map on p. 39). Sampling was done from mid-October to mid-December each year, at four sites along the shoreline at each of the sampling locales. Mussels selected for analysis were in the 50 - 60 mm size range (DEP 2010). All samples were analyzed for aluminum (Al), arsenic (As), cadmium (Cd), copper (Cu), iron (Fe), nickel (Ni), lead (Pb), zinc (Zn), silver (Ag) and mercury (Hg), PAHs, PCBs pesticides, dioxins and furans. Samples with elevated levels are noted in the table. Note that elevation of Al and Fe (which are common and relatively non-toxic constituents of clay and soil minerals) often corresponds to high intake of suspended sediment and may relate to gut contents rather than tissue levels.

Pesticides sampled include the sum of DDTs (dichlorodiphenyl-trichloroethylene) and breakdown products. While the highest DDT levels were seen in Long Island, all Maine samples were considered to be in the low range nationally, based on National Status and Trends Mussel Watch data (NOAA 2008). Dieldrins and chlordanes were also in the low range in Maine samples. Elevated levels for the sum of organochlorine pesticides as compared to...
other data from the Gulf of Maine are noted in the table. In 2009, samples were also collected for additional pesticides: organophosphates, triazines, pyrethroids and organonitrogens. Those pesticides were not at detectable levels in the Maine samples tested (DEP 2010).

### Temporal Trends in Casco Bay

Where data from the same sites are taken over time, it may be possible to compare the levels of pollutants, and observe whether there is any apparent temporal trend. Maine DEP undertook an analysis of temporal trends for selected metals in mussel samples collected from 1987 to 2008 (DEP 2009). Three Casco Bay sites were included: East End Beach in Portland, and Spring Point and Middle Fore River, both in South Portland. The results indicated that:

- Cadmium showed a stable or decreasing trend.
- Copper was relatively stable through time.
- Zinc was relatively stable through time (DEP 2009).
Comparison of lead levels in past and recent samples suggests that for some sites in Casco Bay, lead levels have declined over time. (See the bar graph above.)

**Trends in Mussel Toxics Across the Gulf of Maine: Gulfwatch Data**

Gulfwatch is a joint US/Canada blue mussel monitoring program funded through the Gulf of Maine Council on the Environment. Since 1991, the program has monitored mussels to help identify temporal and spatial trends in ecosystem exposure to toxic compounds throughout the Gulf. Three sites sampled from 2000-2009 lie within the Casco Bay watershed: Portland Harbor (sampled five times in that period), Presumpscot River (sampled three times) and Royal River (sampled twice).

Most metals have decreased over time (units are µg/g dry weight).
Conclusions

Most areas of Casco Bay and the Maine coastline that are located away from human activity have measurable but not elevated levels of toxic chemicals (based on Maine reference conditions and Gulfwatch 85th-percentile values). Elevated levels tend to occur where past manufacturing has left a legacy of pollutants in the sediment; in harbors and commercial port areas; at the mouths of rivers; and in developed areas where runoff is carried into coastal waters from impervious surfaces (see Indicator 2). In the polluted Inner Fore River, for example, historical upstream industry, inflow from the Stroudwater River, and runoff from the Portland Jetport and the Maine Mall all contribute to the toxic body burden of resident mussels. At East End Beach, another affected area, urban runoff, leachate from a dump, riverine inputs from the Presumpscot, and nearby dense residential development all contribute to pollution levels.

The human activity-related pattern of mussel contamination seen by Maine DEP’s mussel sampling efforts and by the Gulfwatch regional sampling program is also observed in the distribution of sediment contamination in the Bay (see Indicator 10). There is some positive news. The Gulfwatch data suggest that metal levels in mussels (and in the ecosystem) are declining across the Gulf of Maine, including Casco Bay. The Maine DEP data also support the conclusion that lead levels have dropped at several Casco Bay sites over time.
